

Brain cholesterol regulates Alzheimer's plaques, study reveals

August 13 2021

Depletion of cholesterol in astrocytes (right) directly removes amyloid plaques and phosphorylated Tau (left, orange clusters) in an Alzheimer's mouse model. Credit: Scott Hansen Lab, Scripps Research, Jupiter, Florida.

A team co-led by scientists at Scripps Research has used advanced imaging methods to reveal how the production of the Alzheimer's-associated protein amyloid beta ($A\beta$) in the brain is tightly regulated by cholesterol.

Appearing on line Thursday ahead of print in the Aug. 17 issue of the *Proceedings of the National Academy of Sciences (PNAS)*, the scientists' work advances understanding of how Alzheimer's disease develops and underscores the long-underappreciated role of brain [cholesterol](#). The findings also help explain why genetic studies link Alzheimer's risk to a cholesterol-transporting protein called apolipoprotein E (apoE).

"We showed that cholesterol is acting essentially as a signal in neurons that determines how much A β gets made—and thus it should be unsurprising that apoE, which carries the cholesterol to neurons, influences Alzheimer's risk," says study co-senior author Scott Hansen, Ph.D., an associate professor in the Department of Molecular Medicine at Scripps Research, Florida.

The other co-senior author of the study was Heather Ferris, MD, Ph.D., assistant professor in the Department of Medicine at the University of Virginia School of Medicine. The study's first author, Hao Wang, is a graduate student in the Hansen lab.

Understanding A β

A type of A β in the Alzheimer's brain can form large, insoluble aggregates that gather in extensive clumps or "plaques"—one of the most prominent features of the disease at autopsy. Genetic evidence correlates the production of a subtype of A β with Alzheimer's, yet A β 's role in both the healthy brain and in disease remain a subject of debate, after many clinical trials of A β -clearing therapeutics have struggled to show a benefit.

In the new study, Hansen and his colleagues take a close look at cholesterol's connection to A β production. Cholesterol's role has been suggested by various prior studies but never confirmed directly, due to technological limitations. The scientists used an advanced microscopy

technique called super-resolution imaging to "see," in cells and in the brains of live mice and tracked how cholesterol regulates A β production.

They focused on cholesterol produced in the brain by essential helper cells called astrocytes, and saw it was carried by apoE proteins to the outer membranes of neurons. There, it appeared to help maintain clusters of cholesterol and related molecules colloquially referred to as "[lipid rafts](#)." Lipid rafts are not yet well understood, in part because they are too tiny to image with ordinary light microscopes. With improved technology, they are increasingly appreciated as hubs where signaling molecules come together to carry out key cellular functions.

The protein from which A β is produced, APP, also sits in neuronal membranes. The researchers showed that apoE and its cholesterol cargo bring APP into contact with nearby lipid rafts. There, in the rafts, enzymes that cleave APP to form A β are found. They found that blocking the flow of cholesterol would take APP out of contact with lipid rafts, thereby effectively preventing A β production.

Cholesterol molecules on the surface of certain brain cells called astrocytes may facilitate production of Alzheimer's-associated plaques, according to research in PNAS from Scott Hansen, PhD, associate professor of molecular medicine at Scripps Research in Jupiter, Florida. Cholesterol and brain health

The scientists then did a series of experiments in aged "3xTg-AD" mice, which are genetically engineered to overproduce $A\beta$, to develop $A\beta$ plaques, and broadly to model Alzheimer's. They found that when they shut off astrocyte cholesterol production in the mice, $A\beta$ production plummeted to near-normal, and $A\beta$ plaques virtually disappeared. Another classic Alzheimer's sign usually seen in these mice is the

accumulation of tangled aggregates of a neuronal protein called tau—and those disappeared too.

By confirming and clarifying the role of astrocyte-produced cholesterol in A β production, the study suggests that targeting this process is worthy of exploration for potential to prevent Alzheimer's progression.

Hansen notes, however, that cholesterol is needed by the brain for many other processes, including the maintenance of normal alertness and cognition. His laboratory discovered in a 2020 study that severely interrupting the effect of cholesterol in neurons by general anesthetics can induce unconsciousness via a shared mechanism.

"You couldn't just eliminate cholesterol in neurons, cholesterol is needed to set a proper threshold for both A β production and normal cognition," Hansen says.

The findings offer new evidence of the underlying factors advancing development of Alzheimer's. A common variant of the apoE gene, known as the E4 variant, is the largest risk factor for late-onset Alzheimer's, and Hansen and colleagues found evidence in the study that this variant, compared to the more common, lower-risk E3 variant, somehow boosts APP's association with lipid rafts, which thus boosts A β production.

Hansen and his laboratory are currently studying how apoE's transport of cholesterol and maintenance of lipid rafts in the brain impacts not only A β production but also brain inflammation—another feature of Alzheimer's that contributes to destruction in the brain but has murky causes.

"There is the suggestion here of a central mechanism, involving cholesterol, that could help explain why both A β plaques and

inflammation are so prominent in the Alzheimer's [brain](#)," Hansen says.
