

Protein responsible for leukemia's aggressiveness identified

27 April 2018

Researchers have identified a protein critical for the aggressiveness of T-cell leukemia, a subtype of leukemia that afflicts children and adults.

proapoptotic unfolded protein response, *Leukemia* (2018). [DOI: 10.1038/s41375-018-0141-x](https://doi.org/10.1038/s41375-018-0141-x)

The identification of ubiquitin-fusion degradation 1 (UFD1) allows for better understanding what causes [leukemia](#) to progress and become highly aggressive and [treatment](#)-resistant, and may lead to a new treatment for this type of cancer.

Provided by Boston University School of Medicine

Leukemia is a [blood cancer](#) that affects individuals of all ages. T-cell is a particularly aggressive subtype of leukemia which is fatal in 20 percent of children and 50 percent of adults.

Researchers at Boston University School of Medicine (BUSM) conducted combined analyses of patient samples and experimental models of leukemia that resemble a major subtype of the disease. They found that UFD1 is expressed in this aggressive subtype of leukemia, and reducing its protein levels by approximately 50 percent inhibited leukemia development and progression without impacting the overall health of the [experimental models](#).

"Because of its discouraging odds, and because current treatments remain highly toxic to patients, continued research efforts are needed to understand what causes this disease's aggressiveness and its resistance to treatment, and to identify alternative treatments that are effective but minimally toxic," explained corresponding author Hui Feng, MD, PhD, assistant professor of pharmacology and medicine at BUSM. "This research identifies the potential of targeting UFD1 to treat aggressive leukemia without causing high toxicity to normal tissues."

These findings appear in the journal *Leukemia*.
