Researchers at The University of Alabama have shown a tiny worm can

replicate genetic causes of Alzheimer's disease, expanding the breadth of preclinical models for the disease.

"This is exciting because it validates the idea that we can use this simple system as a way to more rapidly tease out factors that might contribute to Alzheimer's," said Dr. Guy Caldwell, University Distinguished Research Professor.

Caldwell is co-author of a paper on the findings published in the journal *Disease Models and Mechanisms*. The work was supported by a Howard Hughes Medical Institute Collaborative Innovation Award.

The lead author is former UA doctoral student, Dr. Edward Griffin, now a post-doctoral researcher at the University of Alabama at Birmingham department of neurology.

Other co-authors include Dr. Kim Caldwell, UA professor of biological sciences, and Dr. Laura Berkowitz, UA lab manager and research associate. Also four other UA students were co-authors, including graduate students Samuel Scopel of St. Louis, Missouri; and Cayman Stephen of Lafayette, La.; along with undergraduate students Adam Holzauer of Pontiac, Il.; Madeline Vaji of Cleveland, Ohio; and Ryan Tuckey of Middle Town, Maryland.

The Caldwells, along with their students, use tiny roundworms known as *C. elegans*, which share roughly half their genes with humans, to study human diseases. Its basic features allow inexpensive and rapid testing for a range of neurological diseases, as researchers can induce similar effects in the worm. They can be an important step in evaluating therapies in a chain of discovery from cells to animal models and, eventually, humans.

The worms have been used to study aspects of Alzheimer's [disease](#)

before, but now the UA researchers were able to show that humanized worms can be generated to emulate conditions seen in humans with [genetic variation](#) in a certain protein called Apolipoprotein E, or ApoE, for short.

"The worms recapitulate the clinical trend of Alzheimer's risk seen in humans that harbor these heritable differences, therefore the new animal models open up the door to future mechanistic analyses and drug discovery," Dr. Guy Caldwell said.

The exact cause of Alzheimer's is unknown, but the effects of the disease on the brain include decreasing communication between the brain's cells as neurons and their synapses are lost, leading to atrophy of part of the brain as the disease progresses. A person goes from short-term memory loss to dementia and eventual loss of bodily functions.

Afflicting nearly 30 million people worldwide, Alzheimer's typically occurs in people older than 65, although early-onset Alzheimer's does happen.

A characteristic of the disease is the folding and tangling of the protein amyloid beta into plaques as it aggregates in excessive amounts in the brain, contributing to the loss of neuron connections. This is found in nearly 70 percent of late-life Alzheimer's.

Although the cause of amyloid beta plaques is not clear, a strong genetic risk is variation of the APOE gene. In fact, the variant, APOE $\epsilon$ 4, is found in more than 40 percent of patients. If two of the APOE $\epsilon$ 4 genes are inherited from parents, a person has a 15-fold increased risk of getting Alzheimer's, although the chances of not getting it are still greater than a diagnosis. The presence of APOE $\epsilon$ 4 can be detected in commercial genetic tests commonly used for ancestry discovery.

During the research that led to the paper, Griffin and the team induced neurodegeneration using human amyloid beta in the worms and tested it with three variants of APOE – APOE $\epsilon$ 2, thought to provide protective measures against Alzheimer's; APOE $\epsilon$ 3, a seemingly neutral genetic variant for the disease; and APOE $\epsilon$ 4.

"We took a worm model with amyloid beta that we previously found could already be used to discern genes and drug candidates related to Alzheimer's, as reported in a 2011 article in *Science*, and now added these major genetic risk factors for the disease to it," Caldwell said.

The UA researchers found the APOE make-up in the worm did affect neurodegeneration. In the worms, APOE $\epsilon$ 4 did not increase neurodegeneration, but the protection against it was lost. Strikingly, neurons in worms with APOE $\epsilon$ 2 were protected, as observed in humans. Worms with any APOE variant but no [amyloid beta](#) were fine.

"It's that combination that seems to be toxic to the neurons," Caldwell said.

APOE also affected the lifespan of the worms, with APOE $\epsilon$ 4 showing comparatively decreased survival. That's a key to understanding Alzheimer's as it has become more prevalent as people in developed societies live longer, Caldwell said.

"Because the [worms](#) showed distinctions in lifespan and neurodegeneration, one of the hopes going forward is that we can use these models for preclinical drug discovery," he said. "To say that Alzheimer's represents an unmet and urgent societal challenge is an understatement, and we need an all-hands-on-deck approach to combat it sooner."
