

Why a large hip circumference protects from type 2 diabetes and cardiovascular disease

June 18 2020

If fat is stored on the hips and thighs, this could offer protection against type 2 diabetes and cardiovascular diseases among other things. Credit: Norbert Stefan

In a *Lancet Diabetes & Endocrinology* review article, Norbert Stefan from the German Center for Diabetes Research (DZD), the University Hospital of Tübingen and the Boston Children's Hospital highlights why and to what extent a large hip circumference, an estimate of increased fat mass in the lower part of the body, protects from type 2 diabetes and cardiovascular diseases (CVD). He also provides new information that a high amount of hip and leg fat mass is very important to retain metabolic health. In addition, he discusses lifestyle modifications and pharmacological interventions that improve body fat distribution and exemplifies how a focus on lower body fat mass helps clinicians in risk assessment and patient communication.

An increased [fat mass](#) is an important risk factor for the worldwide increase in type 2 diabetes and CVD. However, for a given fat mass, there is a large variability in the risk of these cardiometabolic diseases. For example, some lean people unexpectedly have a risk of type 2 diabetes and CVD that is similar to the increased risk that is observed in most people who have obesity. What both of these phenotypes have in common is an increased [upper body](#), and more specifically, an increased visceral (inside the belly), fat mass. As a result, much focus has been given on the strong predictive power of upper body obesity.

However, comparisons to rare diseases such as lipodystrophy (dramatic rarefication of fat mass under the skin) and studying genetically determined fat distribution in the [general population](#), suggest that an impaired ability to expand fat in the lower part of the body is also very important for predicting the incidence of these diseases.

Stefan highlights mechanisms that result in energy storage in different fat depots of the body, or ectopically, in organs such as the liver, the pancreas and the heart. Then he discusses studies showing to what extent measurement of fat in the lower part of the body is helpful to estimate the risk of type 2 diabetes and CVD. In this respect, recently published

landmark studies provide genetic support that a low amount of estimated visceral fat and a high amount of lower body fat may be equally important to retain cardiometabolic health. He then provides novel information from a magnetic resonance imaging study supporting this hypothesis.

The author then discusses mechanisms that may drive a dramatic redistribution of fat from the lower to the upper part of the body during aging. Changes of sex hormone levels and signaling during lifetime are considered very important, both in men and in women. He also highlights strategies, related to changes in lifestyle, or pharmacological treatment in diseases associated with disproportionate fat distribution, such as nonalcoholic fatty liver disease or a lipodystrophy-like phenotype, that help to hinder such fat-redistribution.

Finally, he exemplifies how the focus on lower [body](#) fat [mass](#) helps health care providers to better assess the risk of cardiometabolic diseases and to communicate this risk with their patients.
