

Cells that control hunger affect brain structure and function

July 29 2022, by Mallory Locklear

Neurons in the hypothalamus (B) project to the ventral tegmental area (C), where cells send connections to the prefrontal cortex (A). Through this pathway, AgRP cells in the hypothalamus affect cortical structure and function. Credit: Yale University

The prefrontal cortex region of the human brain is responsible for a range of complex functions from decision-making to certain types of memory. When something goes wrong in this part of the brain, it can be

very detrimental for cognition and behavior. In fact, dysfunction in the prefrontal cortex is linked to several psychiatric illnesses, including schizophrenia and major depressive disorder.

Yale researchers and their colleagues in Hungary have discovered that cells in the hypothalamus—an area of the [brain](#) that controls functions like hunger and body temperature—play a major role in shaping the structure and function of the [prefrontal cortex](#) in mice, a finding that could offer clues into how this [region](#) of the brain is altered in disease and open new avenues for treatment.

They reported their findings July 29 in the journal *Molecular Psychiatry*.

For the study, the researchers focused on agouti-related peptide (AgRP) neurons located in the hypothalamus region of the brain. These neurons control hunger and regulate both feeding behaviors and non-feeding behaviors like reward-seeking and offspring-parent bonding, among others.

When the researchers impaired AgRP neurons in mice, they found there were fewer neurons in the prefrontal cortex than there were in healthy animals.

"The neurons that remained were smaller than usual and behaved differently in response to cues from the body and signals from surrounding cells," said Tamas Horvath, the Jean and David W. Wallace Professor of Comparative Medicine at Yale and senior author of the study.

AgRP neurons do not have strong direct connections to the cortex. But they do project to other [brain regions](#) that connect to the prefrontal cortex. Horvath and his colleagues found that the neurons in one of these areas—a midbrain region known as the [ventral tegmental area](#)—were

overactive when AgRP neurons were impaired. Those overactive neurons then released more dopamine, a neurotransmitter, in the prefrontal cortex than is typical in healthy mice, which, in turn, negatively affected mouse [behavior](#). For instance, they found that the mice moved around much more and had abnormal startle responses.

It makes sense that these [neurons](#) that control hunger and feeding would affect the cortex and behavior, says Horvath.

"When you are hungry, you need all of your behaviors lined up so you can find food and eat it," he said. "And when you are no longer hungry, you have to change your behaviors to focus on what's important in that moment."

After uncovering the effects impaired AgRP cells had on the cortex, the researchers then tried to avert them. They found that clozapine—a type of antipsychotic that blocks dopamine from acting and is used to treat schizophrenia—was able to prevent some of these problems, including neuron loss, when given at the right time.

When it comes to these cortical changes, Horvath said, the timing is crucial. In the study, impairments began to emerge during puberty when the brain is still developing and vulnerable. That's also when clozapine administration had an impact. "And this tells us that if you play with homeostatic functions in that specific time period, say by dieting or overeating, you can have long-lasting effects on your cortical functions," he said.

The importance of this period of development may shed light on psychiatric illness, which can often emerge in late adolescence, and why substance use during that time can have long-lasting effects on behavior, physiology, and disease.

These findings may also provide a new target for treatment. AgRP cells in the hypothalamus are outside of the [blood-brain barrier](#), a feature of the brain that protects it from harmful substances and prevents many medications from reaching brain tissue.

"This means these cells are readily available for intervention," said Horvath. "Perhaps they can be exploited to alter disorders of higher brain regions."

The study also adds to a growing body of evidence that the function of the cortex is influenced by more primitive regions of the brain and by other parts of the body. Horvath recently showed how AgRP cells can also affect the [cortex](#) via mediation of the liver.

"The fundamental message here is that in the brain, there is very diffuse communication through different pathways," said Horvath. "Primitive areas like the hypothalamus influence higher cortical regions through innumerable number of communications, which includes brain processes, but also peripheral tissues. We are back to the debate between Camillo Golgi and Ramón y Cajal, who shared the Nobel Prize in 1906, but disagreed on the principles of how the brain works. Our results seem to favor forgotten arguments of Camillo Golgi."
